ABSTRACT

This report represents the first chapter of a book in preparation on inference and data analysis in reliability and life testing. The point of view adopted differs from that of most books on the subject in the following basic respect: **Prior information available to the reliability analyst is utilized fully in a formal statistical fashion.** Experience accumulated in helping engineers, quality assurance managers, scientists, biostatisticians, and others who must make estimates and reach decisions from either planned experiments or retrospective data has shown us that the point of view adopted throughout the book has resulted in useful solutions to real-life problems. By contrast, more classical statistical methods have often proven inadequate in many practical problems simply because the data available are insufficient to reach conclusions with a desired degree of assurance.

The book is intended primarily for actual use by the engineering and scientific practitioner, rather than for theoretical study and philosophical analysis by the statistician. Thus we omit a philosophical justification of the methods presented; rather, we rely on the fact that they have led to useful answers to problems that have arisen in practice.

One final point: Many of the methods and results are original and have not appeared in the literature. This fact has led us to issue the chapters as reports under our research grants.
1. BASIC CONCEPTS

To begin with, we suppose the life test data consist of observed complete lifetimes \( x_1, x_2, \ldots, x_n \) on \( n \) units. For example, Table 1.1 lists ordered lifelengths of 100 Kevlar 49/Epoxy strands subjected to a high static load (Barlow, Toland and Freeman (1979)). An exploratory data analysis indicates that an exponential life distribution may be appropriate for analyzing these lifelengths. Thus, we assume that the observations constitute a sample of \( n \) independent, identically distributed random variables with distribution \( F \) given by (0.1). Although we assume a fixed \( \lambda \) exists which specifies \( F \), we are uncertain as to the true value of \( \lambda \), and seek a method which uses the data to express probabilistically our uncertainty regarding the true value of \( \lambda \).

The first step is to evaluate the joint probability density of the random lifetimes \( X_1, \ldots, X_n \) evaluated at the observed values \( x_1, \ldots, x_n \). Since we are assuming that \( X_1, \ldots, X_n \) are independent given \( \lambda \), the joint density of the observed values is:

\[
(1.1) \quad \prod_{i=1}^{n} f(x_i \mid \lambda) = \lambda^n \exp \left( -\lambda \sum_{i=1}^{n} x_i \right).
\]

The Likelihood Function

To focus attention on the parameter of interest $\lambda$, we regard (1.1) as a function of $\lambda$ and call

$$L(\lambda \mid x_1, \ldots, x_n) = \lambda^n \exp \left(-\lambda \sum_{i=1}^{n} x_i \right)$$

the likelihood function. (The likelihood, although a function of the parameter $\lambda$, is not a probability density in the parameter. Hence the vertical bar in $L$ does not signify a conditional probability, as it usually does.) The likelihood function provides a means of quantifying the information contained in the data concerning the unknown true value of the exponential parameter $\lambda$.

Suppose a unique value $\hat{\lambda}$ of $\lambda$ exists maximizing the likelihood function; then we call $\hat{\lambda}$ the mode of $L(\lambda \mid x_1, \ldots, x_n)$ and the maximum likelihood estimator (MLE) of $\lambda$. In general, the MLE, when it exists, is a very useful concept.

To simplify the calculation of $\hat{\lambda}$, we use the fact that the maximum of the likelihood, when it exists, is achieved at the same value of $\lambda$ as is the maximum of the logarithm of the likelihood. Thus we compute

$$\frac{d}{d\lambda} \ln L(\lambda \mid x_1, \ldots, x_n) = \frac{n}{\lambda} - \sum_{i=1}^{n} x_i,$$

and set the derivative equal to $0$. We readily obtain

$$\hat{\lambda} = n \left( \sum_{i=1}^{n} x_i \right)^{-1},$$

and verify that $\hat{\lambda}$ maximizes $L(\lambda \mid x_1, \ldots, x_n)$ for fixed $x_1, \ldots, x_n$. 
The MLE \( \lambda \) may be a very satisfactory estimator of the unknown failure rate \( \lambda \) for moderate to large sample sizes \( n \). (Caution: For more complex life distribution models involving an infinite number of unknown parameters, the MLE of the parameters may be quite misleading. See Marshall and Proschan (in process) for an example in which the MLE converges to the \textit{wrong} set of the parameter values even though the sample size tends to infinity. Also see Lindley (1972), p. 12, for a similar two parameter example and Basu (1975), p. 34, for a one parameter example.) In the present case of estimation of the single parameter \( \lambda \) of the exponential, our uncertainty as to the true value of \( \lambda \) stems from the fact that our sample size \( n \) is finite.

A good way to express our uncertainty concerning \( \lambda \) is by means of a \textit{probability distribution} for \( \lambda \). To display explicitly this point of view, we let \( \tilde{\lambda} \) denote a random variable expressing our uncertainty concerning the unknown true value of \( \lambda \).

\textbf{Bayes' Theorem}

A key theorem based on this point of view is the fundamental Bayes' Theorem. It provides a method for computing the probability density of the random variable expressing our uncertainty concerning the parameter conditioned on the observed data.

\textbf{1.2 Theorem (Bayes' Theorem)}

Let (a) \( X \) and \( \tilde{\theta} \) be random variables with joint probability density \( p(x, \theta) \), (b) \( p(x \mid \theta) \) and \( p(\theta \mid x) \) denote the corresponding conditional densities, and (c) \( \pi(\theta) \) denotes the marginal density of \( \tilde{\theta} \). Let \( \Theta \) be the parameter space, i.e., \( \theta \in \Theta \). Then
(1.3) \[ p(\theta \mid x) = \frac{p(x \mid \theta) \pi(\theta)}{\int p(x \mid \theta) \pi(\theta) d\theta} . \]

**Proof:**

The joint density \( p(x, \theta) \) of \( X \) and \( \theta \) may be written as:

\[ p(x, \theta) = p(x \mid \theta) \pi(\theta) . \]

By definition of a conditional probability density,

\[ p(\theta \mid x) = p(x, \theta)/p(x) , \]

when \( p(x) > 0 \), where

\[ p(x) \overset{\text{def}}{=} \int p(x \mid \theta) \pi(\theta) d\theta . \]

By combining the three equalities in the steps just above, we immediately obtain the desired conclusion (1.3).

**Prior and Posterior Distributions**

Before analyzing statistical data, it is helpful and efficient to assess relevant information. A convenient way to accomplish this is to formulate a probability density on the parameter(s) of the model selected. We realize that generally we cannot be certain that the model selected is the "true" model and that the prior distribution for the parameter(s) specified for the model is perfectly correct. However, once we select an appropriate model, and a prior distribution on the parameter space for that model, we may complete a useful and informative data analysis in an unambiguous fashion using only the standard calculus of probability theory.
The Prior Density

First, we confine our choice of prior densities to proper densities; i.e., \( \pi(\lambda) \) satisfies

\[
\int_0^\infty \pi(\lambda) d\lambda = 1.
\]

Next, to motivate the concept of a natural conjugate prior for \( \tilde{\lambda} \), we suppose that in the particular problem under discussion, we have very little prior information concerning \( \tilde{\lambda} \). It seems natural to assume initially a rectangular prior density:

\[
\pi_o(\lambda) = \begin{cases} 
M^{-1} & \text{for } 0 \leq \lambda \leq M \\
0 & \text{otherwise},
\end{cases}
\]

where \( M \) is a very large number (say \( M = 10^{12} \)). Under this assumption on the prior density, we assign the same probability that \( \tilde{\lambda} \) is in any interval in \( [0,M] \) of a specified length. For example, the a priori probability that \( 5 \leq \tilde{\lambda} \leq 10 \) is the same as the a priori probability that \( 19 \leq \tilde{\lambda} \leq 24 \).

The Posterior Density

Suppose we have observed a sample of \( n \) lifelengths \( x_1, \ldots, x_n \) having joint density \( p(x_1, \ldots, x_n \mid \lambda) \). By Bayes' Theorem, the posterior density of \( \tilde{\lambda} \) is given by:

\[
\pi_1(\lambda \mid x_1, \ldots, x_n) = \frac{p(x_1, \ldots, x_n \mid \lambda)\pi_o(\lambda)}{\int_0^\infty p(x_1, \ldots, x_n \mid \lambda)\pi_o(\lambda) d\lambda}.
\]
Recall that the likelihood $L(\lambda \mid x_1, \ldots, x_n) = p(x_1, \ldots, x_n \mid \lambda)$, namely the probability density of the observed outcome considered as a function of the parameter $\lambda$. Thus we may write:

$$
\pi_1(\lambda \mid x_1, \ldots, x_n) = \frac{L(\lambda \mid x_1, \ldots, x_n)\pi_0(\lambda)}{\int_0^\infty L(\lambda \mid x_1, \ldots, x_n)\pi_0(\lambda)\,d\lambda}.
$$

Since $\lambda$ has been integrated out in the denominator, the denominator is now a constant with respect to $\lambda$. Hence

$$
\pi_1(\lambda \mid x_1, \ldots, x_n) \propto L(\lambda \mid x_1, \ldots, x_n)\pi_0(\lambda),
$$

where $\propto$ means "proportional to." Thus the right hand side is the same as the left hand side up to a constant which does not depend on the parameter $\lambda$. Notice that since the data $x_1, \ldots, x_n$ have already been observed, the data are not considered variables at this stage of the analysis.

Assuming the rectangular prior $\pi_0(\lambda) = \lambda^{-1}$ for $0 \leq \lambda \leq M$, we obtain for the posterior density of $\lambda$:

$$
\pi_1(\lambda \mid x_1, \ldots, x_n) = M^{-1}\lambda^n \exp\left(-\lambda \sum_{i=1}^n x_i\right)/M^{-1}\int_0^M \lambda^n \exp\left(-\lambda \sum_{i=1}^n x_i\right)\,d\lambda.
$$

For $n^{-1} \sum_{i=1}^n x_i \gg M^{-1}$, this is approximately:

$$
(1.4) \pi_1(\lambda \mid x_1, \ldots, x_n) = \left(\sum_{i=1}^n x_i\right)^{n+1}\lambda^n \exp\left(-\lambda \sum_{i=1}^n x_i\right)/\Gamma(n + 1),
$$
where $\Gamma(n + 1) = \int_0^\infty u^n e^{-u} du$ is the gamma function. In computing (1.4) we have used the fact that $\int_0^\infty c^{n+1} u^n e^{-cu} du = \Gamma(n + 1)$ for all $c > 0$.

Thus, if we assume initially a rectangular prior on $[0,M]$, $M$ large, the resulting posterior density is approximately of the form:

$$b^a \lambda^{a-1} e^{-b\lambda} / \Gamma(a) \text{ for } \lambda > 0, \tag{1.5}$$

where $a, b > 0$. Note that the posterior density is approximately a gamma density with shape parameter $a = n + 1$ and scale parameter $b = \sum_{i=1}^n x_i$.

Now, suppose we obtain an additional independent random sample of lifetimes $y_1, y_2, \ldots, y_m$. Then it is reasonable to use as our new prior density, the posterior density (1.4) obtained from the previous sample. Using as our new prior:

$$\pi_1(\lambda) = b^a \lambda^{a-1} e^{-b\lambda} / \Gamma(a)$$

with $a = n + 1$ and $b = \sum_{i=1}^n x_i$, we obtain:

$$\pi_2(\lambda \mid y_1, \ldots, y_m) = \frac{\lambda^m \exp \left( -\lambda \sum_{i=1}^m y_i \right) b^a \lambda^{a-1} e^{-b\lambda} / \Gamma(a)}{\int_0^\infty \lambda^m \exp \left( -\lambda \sum_{i=1}^m y_i \right) [b^a \lambda^{a-1} e^{-b\lambda} / \Gamma(a)] d\lambda},$$

or

$$\pi_2(\lambda \mid y_1, \ldots, y_m)$$

(1.6)

$$= \left( b + \sum_{i=1}^m y_i \right)^{m+a} \lambda^{m+a-1} \exp \left( -\lambda \left( b + \sum_{i=1}^m y_i \right) \right) / \Gamma(m + a).$$
Thus, \( a \) is increased by the additional number \( m \) of observed failures and \( b \) increased by the additional total time on test \( \sum_{i=1}^{m} y_i \) to obtain the new posterior density \( \pi_2 \); note however, that the form of the posterior density, the gamma, is retained.

Because of this preservation property (the gamma prior used in the exponential model leads to a gamma posterior), the gamma prior is called the "natural conjugate" prior for the parameter \( \lambda \) in the exponential model. More generally, a conjugate prior distribution is "conjugate" with respect to a given statistical model if the form of the posterior is the same as that of the prior; the parameters of the posterior distribution will of course, change in accordance with the data observed. In the present case, we can interpret the prior density parameter \( a - 1 \) (if \( a \) is an integer \( > 1 \)) as the number of observations in a previous experiment (actual or conceptual) and \( b \) as the corresponding total time on test.

In the present exponential model, the gamma prior for \( \lambda \) is mathematically convenient and has intuitive interpretation. However, the analyst is not confined to a choice with this family. Rather, the choice of the prior distribution should always reflect the best possible specification of the analyst's prior information concerning the unknown parameter. Thus, in reporting the results of the data analysis, the analyst should present his specification of the prior and the basis for his choice. In Chapter 3, we will discuss in more detail the assignment of the prior distribution.

1.3 Example

Table 1.1 lists the observed lifetimes of 100 organic fiber strands subjected to a static load of 8009 grams which corresponds to 80% of their mean rupture strength. Experience has shown that the lifetime
of an organic fiber strand at relatively high stress can be reasonably well fitted by an exponential life distribution. Thus, we assume

\[ P[\text{Lifelength} > x] = e^{-\lambda x} \quad \text{for} \quad x \geq 0 , \]

where \( \lambda \) is unknown. As described above, we calculated the MLE of \( \lambda \) as:

\[ \tilde{\lambda} = 4.78 \times 10^{-3} / \text{hour} . \]

Since the sample size of 100 is moderately large, the likelihood

\[ L(\lambda \mid x_1, \ldots, x_{100}) = \lambda^{100} \exp\left(-\lambda \sum_{i=1}^{100} x_i\right) \]

will override in importance the retangular prior:

\[ \pi_0(\lambda) = M^{-1}, \quad 0 < \lambda \leq M , \]

when \( M \gg \tilde{\lambda} \). From the prior \( \pi_0 \) we calculate the posterior density of \( \lambda \) to be approximately a gamma with parameters \( a = 101 \) and \( b = 20,917 \) hours. (Note that \( a \) is dimensionless while \( b \) is measured in hours). See Figure 1.1. The mode of the posterior density may be used to estimate \( \lambda \). In Chapter 2 we discuss other estimators.

**Sufficient Statistics**

By a statistic, we mean a function (possibly vector-valued) of the data. A statistic, of course, is often used to estimate an unknown parameter of interest. Clearly, the complete set of data observed is trivially a statistic. For a large set of data, working with all of the observations may be tedious or even unmanageable. Thus, we are motivated to find a statistic of smaller dimensionality like the sample mean (of
FIG 1.1
COMPUTER PLOT OF POSTERIOR GAMMA DENSITY OF LAMBDA
dimension one) or the number of failures and the total time on test (of dimension two), but which contains all of the information in the sample concerning the parameter. Preferably, we would like to estimate the parameter using a statistic of lower dimensionality which summarizes all of the information in the sample. We will often use $D$ to denote the observed data. For example, $D$ could stand for the vector of observed values $(x_1, x_2, \ldots, x_n)$. Later it will denote more complicated data sets. This motivates:

1.4 Definition

Let $D$ denote the data with probability density $p(D \mid \theta)$ indexed by the parameter $\theta$. A statistic $s$ is sufficient for $\theta$ if and only if for every prior $\pi(\theta)$, the posterior

$$\pi(\theta \mid D) = \frac{p(D \mid \theta)\pi(\theta)}{\int_H p(D \mid \theta)\pi(\theta)d\theta}$$

depends on the data $D$ only through the statistic $s$; i.e., for every prior $\pi$, the posterior can be written as $\pi(\theta \mid s)$.

Intuitively, knowing $s$ we are as informed about the parameter $\theta$ as when we know all the data collected.

There may be several sufficient statistics available for estimating a parameter. Clearly, from among these we would prefer to make use of one of lowest dimensionality. For a given parameter, there actually may be more than one sufficient statistic of lowest dimensionality and it may be vector valued.

An easy way to find a sufficient statistic is to examine the likelihood for the kind of factorization displayed in:
1.5 Lemma

Let the likelihood $L(\theta \mid D)$ factor so that:

$$L(\theta \mid D) = g(s \mid \theta) h(D),$$

where $h$ does not depend on $\theta$. Then $s$ is a sufficient statistic for $\theta$.

Proof:

For an arbitrary prior density $\pi$, the corresponding posterior density is given by:

$$\pi(\theta \mid D) = \frac{L(\theta \mid D) \pi(\theta)}{\int_{\mathbb{H}} L(\theta \mid D) \pi(\theta) d\theta} = \frac{g(s \mid \theta) h(D) \pi(\theta)}{\int_{\mathbb{H}} g(s \mid \theta) h(D) \pi(\theta) d\theta} = \frac{g(s \mid \theta) \pi(\theta)}{\int_{\mathbb{H}} g(s \mid \theta) \pi(\theta) d\theta}.$$

The last expression clearly depends on $D$ only through the statistic $s$. Thus by Definition 1.4, $s$ is sufficient for $\theta$.

For example, if $x_1, \ldots, x_n$ are independent lifelengths in the exponential model, given $\lambda$, then $s \overset{\text{def}}{=} \sum_{i=1}^{n} x_i$ is a sufficient statistic for the failure rate $\lambda$ since:

$$L(\lambda \mid x_1, \ldots, x_n) = \lambda^n \exp \left( -\lambda \sum_{i=1}^{n} x_i \right) = \lambda^n e^{-\lambda s}.$$
The Sample Space

The \textit{sample space} is the space or set of possible sample outcomes. If we observe the lifetimes of \( n \) units, the sample space is

\[
S = \{(x_1, x_2, \ldots, x_n) \mid x_i \geq 0, 1 \leq i \leq n\}.
\]

For \( n = 2 \), \( S \) is the positive quadrant; i.e.,

\[
\begin{align*}
\text{FIGURE 1.2}
\end{align*}
\]

However, we may just as well consider another sample space. Suppose we are told only the ordered lifetimes

\[
x(1) \leq x(2) \leq \cdots \leq x(n),
\]

i.e., we no longer know which unit fails at time \( x(1), 1 \leq i \leq n \). The sample space corresponding to the ordered lifetimes is now

\[
S_o = \{(x(1), x(2), \ldots, x(n)) \mid 0 \leq x(1) \leq \cdots \leq x(n)\}.
\]
For $n = 2$, we now have

For sample space (1.7) and the exponential model we have the joint probability density

\[(1.9) \quad p(x_1, x_2, \ldots, x_n | \lambda)\]

\[= \begin{cases} 
\lambda^n \exp\left\{-\lambda \sum_{i=1}^{n} x_i\right\} & x_i > 0, \ 1 \leq i \leq n \\
0 & \text{otherwise}.
\end{cases}\]

For this case $L(\lambda | x_1, x_2, \ldots, x_n) = p(x_1, x_2, \ldots, x_n | \lambda)$.

On the other hand, for sample space (1.7) and the exponential model we have

\[(1.10) \quad p_o(x_{(1)}, \ldots, x_{(n)} | \lambda)\]

\[= \begin{cases} 
n! \lambda^n \exp\left\{-\lambda \sum_{i=1}^{n} x_{(i)}\right\} & 0 \leq x_{(1)} \leq \cdots \leq x_{(n)} \\
0 & \text{otherwise}.
\end{cases}\]
The factor \( n! \) in (1.10) follows from the fact that the ordered observations can result from any one of \( n! \) permutations of the observations \( x_1, x_2, \ldots, x_n \). For this case let

\[
L_o(\lambda \mid x_{(1)}, \ldots, x_{(n)}) = p_o(x_{(1)}, \ldots, x_{(n)} \mid \lambda).
\]

From (1.9) and (1.10) we see that

(1.11) \[ L(\lambda \mid x_1, x_2, \ldots, x_n) \propto L_o(\lambda \mid x_{(1)}, x_{(2)}, \ldots, x_{(n)}) \].

It follows that, for any prior for \( \tilde{\lambda} \), the posterior density for \( \tilde{\lambda} \) will be the same no matter which of the above sample spaces we choose. From (1.11) and Lemma 1.5 we see that the order statistics \( x_{(1)}, x_{(2)}, \ldots, x_{(n)} \) are sufficient for \( \lambda \).
2. SELECTED LIFE TEST SAMPLING PLANS

In this section we illustrate the application of the concepts and methods of Section 1 when estimating under each of several commonly used life test sampling plans.

Sampling Plan (a). Complete Observation Until A Specified Number of Failures Have Occurred

A popular plan consists of putting \( n \) items on test and observing the failure times of the first \( k \) failures, where \( k \) is specified in advance. The motivation for following this plan is to save time in determining an estimate of the exponential failure rate.

Let

\[
x(1) \leq x(2) \leq \cdots \leq x(k), \quad 1 \leq k \leq n,
\]

denote the successive times of failure of the earliest \( k \) failures; \( x(1), \ldots, x(k) \) are called the first \( k \) order statistics in a sample of size \( n \). The likelihood of this observed outcome under the exponential model is given by;

\[
L(\lambda \mid D) = \frac{n!}{1! \cdots 1!(n-k)!} \left[ \prod_{i=1}^{k} \lambda e^{-\lambda x(i)} \right] e^{-(n-k)\lambda x(k)}.
\]

(We follow the usual convention that \( 0! = 1 \).)

Simplifying, we have:

\[
(2.1) \quad L(\lambda \mid D) = \frac{n!}{(n-k)!} \lambda^k \exp \left\{ -\lambda \left[ \frac{1}{k} \sum_{i=1}^{k} x(i) + (n-k)x(k) \right] \right\}.
\]

To verify the expression preceding (2.1), note that the combinatorial coefficient \( \frac{n!}{1! \cdots 1!(n-k)!} \) represents the number of ways of choosing
one observation to correspond to each of \( x_1, x_2, \ldots, x_k \) and \((n - k)\) observations for the \((n - k)\) unobserved failure times, from among the \(n\) failure times (of which only the first \(k\) are actually observed). The product factor represents the joint density of the \(k\) actually observed failure times, given \(\lambda\). Finally, the last factor represents the probability that \((n - k)\) lifelengths each exceed \(x_k\), given \(\lambda\).

The expression in the exponent of (2.1):

\[
\sum_{l=1}^{k} x_l + (n - k)x_k = nx_1 + (n - 1)(x_2 - x_1) + \ldots + (n - k + 1)(x_k - x_{k-1}) \overset{\text{def}}{=} T(x_k)
\]

(2.2)

represents the total time on test until the \(k\)th failure. Note that it is comprised of \(nx_1\) the total time on test observed until the first failure; of \((n - 1)(x_2 - x_1)\), the total time on test observed between the first and second failures; \(\ldots\); and of \((n - k + 1)(x_k - x_{k-1})\), the total time on test observed between the penultimate and the last observed failures. (Of course, it is understood that after an item fails, it is no longer under observation.)

The total time on test statistic turns out to be a very important and useful statistic not only in the exponential model, but also after appropriate generalization, in a large number of other models involving incomplete data. In the exponential model, the total time on test and the number of observed failures constitute a sufficient statistic for \(\lambda\). In the presently considered sampling plan under which \(k\), the number of observed failures is specified in advance, we see from (2.1) that \(T(x_k)\) alone is sufficient for \(\lambda\).

Suppose we assume a gamma prior on \(\lambda\):
\[ \pi(\lambda) = b^a \lambda^{a-1} e^{-b \lambda} / \Gamma(a). \]

Using (2.1), we obtain for the posterior:

\[ (2.3) \quad \pi(\lambda \mid D) = [b + T(x_{(k)})]^{k+a} \lambda^{k+a-1} e^{-\lambda [b + T(x_{(k)})]} / \Gamma(k + a), \]

also a gamma, but with the shape parameter \( a \) of the prior density replaced by \( a + k \) and the scale parameter \( b \) of the prior density replaced by \( b + T(x_{(k)}) \). Note that the increment in the scale parameter is \( T(x_{(k)}) \), the observed total time on test. The mode of the posterior density is:

\[ \lambda^0 = (k + a - 1) / [b + T(x_{(k)})]. \]

It is interesting to note that for \( \pi(\lambda) \equiv c \), the mode of the posterior is exactly the well known MLE:

\[ \hat{\lambda} = k / T(x_{(k)}). \]

However, it should be emphasized that this prior is improper in the sense that \( \int_0^\infty \pi(\lambda) d\lambda = \infty. \)

We would expect that after collecting a set of data from the exponential distribution, we would have more information concerning the unknown parameter \( \lambda \) than before; more precisely, the peakedness of the density of \( \hat{\lambda} \) might increase or the coefficient of variation might decrease. The coefficient of variation of a distribution is the ratio of the standard deviation (assumed finite) to the absolute value of the mean (assumed non-zero). In the case of the gamma prior density, the mean is \( a/b \), the variance is \( a/b^2 \), and so the corresponding coefficient of variation is \( a^{-1/2} \).

Under the present sampling plan, the posterior distribution, given in (2.3), is also a gamma distribution, but with the shape parameter
(the updated "a" value) now \( a + k \). It follows that the coefficient of variation is now reduced to \((a + k)^{-1/2}\). Thus for fixed \( a \), the coefficient of variation decreases roughly as \( k^{-1/2} \), where \( k \) denotes the observed number of failures. This simple calculation gives us a quantitative notion as to our relative uncertainty concerning \( \lambda \) both before and after observation, and therefore concerning the decrease in our uncertainty.

**Sampling Plan (b). Observation Terminated at Fixed Time (Truncated Sampling)**

Suppose \( n \) units are put on life test at time \( t = 0 \) and each is observed until failure or fixed time \( t_o \), whichever occurs first. Given the random outcome \( K = k \) \((0 \leq k \leq n)\) observed failures in \([0,t_o]\), the corresponding likelihood is given by:

\[
L(\lambda \mid D) = \frac{n!}{1! \ldots 1!(n-k)!} \left[ \frac{k \lambda^x(i)}{\prod_{i=1}^{n-k} \lambda e^{-\lambda x(i)}} \right]^{-(n-k)t_o} e^{-\lambda x(i)}
\]

where the product in square brackets is defined as 1 for \( k = 0 \). The verification of the likelihood expression (2.4) is similar to that obtained under the previous sampling plan, leading to the expression preceding (2.1). One key difference is that the number \( n - k \) surviving fixed time \( t_o \) under the present plan is random, while the number \( n - k \) surviving past the \( k^{th} \) failure under the earlier plan is specified in advance.

We may rewrite the likelihood \( L(\lambda \mid D) \) as:

\[
L(\lambda \mid D) = \frac{n!}{(n-k)!} \lambda^k \exp \left\{ -\lambda \left[ \frac{k}{i=1} x(i) + (n-k)t_o \right] \right\}
\]
It is clear from (2.5) and Lemma 1.5 that the pair \( k \) and the total time on test:

\[
T(t_o) = \sum_{i=1}^{k} x(i) + (n - k)t_o
\]

are sufficient statistics for \( \lambda \). Under the present sampling plan, both \( k \) and the \( T(t_o) \) are observed, and thus together constitute the data \( D \).

From (2.5) the MLE is computed as:

\[
\hat{\lambda} = k/T(t_o).
\]

Under the present sampling plan it is possible to observe \( k = 0 \) failures, leading to a MLE of \( 0 \). Such an estimate is intuitively unsatisfactory; in this situation an analysis based on the posterior distribution of \( \tilde{\lambda} \) is preferable.

The posterior density resulting from a gamma prior [see (1.4)] is, using (2.5):

\[
(2.6) \quad \pi(\lambda \mid D) = \left[ b + T(t_o) \right]^{k+a} \lambda^{k+a-1} e^{-\lambda[b+T(t_o)]} / \Gamma(k + a).
\]

Just as in the previous sampling plan, the posterior coefficient of variation is \( (a + k)^{-1/2} \), which is smaller than \( a^{-1/2} \), the prior coefficient of variation.

**Sampling Plan (c). Inverse Binomial Sampling**

A unit is put on test until it fails or reaches a specified age \( t_o \), whichever occurs first. At this time, the unit is replaced by a new unit. This procedure is repeated sequentially until \( k \) (specified
in advance) failures are actually observed. The number \(N\) of units that have to be tested until \(k\) failures are actually observed is, of course, a random variable. For example, we may have only one test chamber and we may be able to test at most one unit at a time.

Let \(Y = \min(X, t_o)\), where \(X\) has exponential density \(\lambda e^{-\lambda x}\), \(x \geq 0\). Then conditional on \(Y < t_o\) and \(T\), the density of \(Y\) is given by:

\[
\lambda e^{-\lambda y} \frac{1}{1 - e^{-\lambda t_o}} \quad \text{for} \quad 0 \leq y \leq t_o.
\]

Thus, if the successive failure ages actually observed are denoted by \(y_1, y_2, \ldots, y_k\), the corresponding conditional joint density is given by:

\[
g(y_1, \ldots, y_k \mid \lambda, y_i < t_o, 1 \leq i \leq k) = \prod_{i=1}^{k} \frac{\lambda e^{-\lambda y_i}}{1 - e^{-\lambda t_o}} = \frac{\lambda^k \exp \left( -\frac{\lambda}{1 - e^{-\lambda t_o}} \sum_{i=1}^{k} y_i \right)}{(1 - e^{-\lambda t_o})^k}.
\]

The probability that \(N = n\) units have to be tested in order to observe \(k\) actual failures is given by

\[
P[N = n \mid \lambda] = \binom{n - 1}{k - 1} \left(1 - e^{-\lambda t_o}\right)^k \left(1 - e^{-\lambda t_o}(n-k)\right) \quad \text{for} \quad n \geq k.
\]

It follows that, given \(N = n\) and observed failure ages \(y_1, y_2, \ldots, y_k\), the corresponding likelihood is:

\[
L(\lambda \mid D) = \binom{n - 1}{k - 1} \lambda^k \exp \left( -\frac{k}{1} \sum_{i=1}^{k} y_i \right) \exp \left[ -\lambda t_o(n-k) \right], \quad 0 < y_i < t_o, \quad i = 1, \ldots, k.
\]

Combining exponentials we obtain:
L(λ | D) = \left( \frac{n - 1}{k - 1} \right)^k \lambda^k \exp \left\{ -\lambda \left[ \sum_{i=1}^{k} y_i + (n - k)t_0 \right] \right\},
(2.7)
0 < y_i < t_0 , i = 1, ..., k .

From Lemma 1.5, we conclude that the total time on test:

T = \sum_{i=1}^{k} y_i + (n - k)t_0

is by itself sufficient for λ since k is fixed in advance.

From (2.7) we also obtain the posterior density for \tilde{λ} based on a gamma prior density as:

(2.8) \quad \pi(\lambda | D) = (b + T)^{k+a} \lambda^{k+a-1} e^{-\lambda(b+T)} / \Gamma(k + a) .

Note the striking resemblance in the posterior density under the three sampling plans so far considered! (Compare (2.8), (2.6), and (2.3).)

Remarks:

In the three sampling plans considered so far, the number k of observed failures and the total time on test T are all that we need from the observations in order to complete our data analysis; the sufficiency of k and T makes this true. Note that this fact holds for any choice of a prior density.

The "stopping rule" in each of the three test plans considered gives no information about the parameter λ, i.e., is noninformative about λ. (As the name implies, the stopping rule is simply the rule which specifies when the testing is to stop. For example, in the sampling plan (a) we test until k failures are observed and then stop further observation.) If the stopping rule were to give information
about the parameter $\lambda$, then the total time on test $T$ and the observed number of failures would not be sufficient for $\lambda$.

Finally, note that in the test plans considered thus far, the MLE is the ratio of the number of observed failures to the total time on test. This simple formula for the MLE holds in most of the testing procedures followed under the exponential model, as we see in this chapter and shall see in Chapter 2.
3. INFERENCE BASED ON MEAN LIFE

Thus far we have discussed inference for the exponential distribution based on the failure rate $\lambda$. For many analysts, the mean life $\theta$ of the exponential distribution may seem to be the more appropriate parameter to estimate. Note that either parameter determines the other in the exponential model since:

$$\theta = \int_0^\infty x \lambda e^{-\lambda x} \, dx = \lambda^{-1}.$$  

Suppose we consider the simplest type of testing plan: $n$ units are put on test and observed until each fails. The corresponding mutually independent lifelengths given $\lambda$ are $x_1, x_2, \ldots, x_n$, constituting a complete sample from the exponential density:

$$f(x \mid \theta) = \theta^{-1} e^{-x/\theta}.$$  

The likelihood of the outcome is given by:

$$(3.1) \quad L(\theta \mid x_1, \ldots, x_n) = \theta^{-n} \exp \left( -\theta^{-1} \sum_1^n x_i \right).$$

Clearly, the MLE of $\theta$ is given by:

$$\hat{\theta} = n^{-1} \sum_1^n x_i.$$  

Suppose now we have very little prior information on the parameter $\theta$. We therefore assume a rectangular prior density on $\theta$ :

$$\pi(\theta) = M^{-1} \quad \text{for} \quad 0 \leq \theta \leq M,$$
where $M$ is large.\footnote{It would be inconsistent mathematically to assume a rectangular prior on both $\lambda$ and $\bar{\theta} = \lambda^{-1}$, even though we have very little prior information on both parameters. (The implications for $\bar{\theta}$ that result from assuming a rectangular prior for $\lambda$ are brought out in Exercise 1.) We assume a rectangular prior for $\bar{\theta}$ here to motivate the use of a natural conjugate prior.} The corresponding posterior density for $\tilde{\theta}$ may be computed approximately, by Bayes' Theorem (Theorem 1.2), as:

\begin{equation}
\pi(\theta \mid x_1, \ldots, x_n) = b^n a^{-a+b+1} e^{-b/a} / \Gamma(a)
\end{equation}

for $\theta, a, b > 0$, where now $a = n - 1$ and $b = \frac{1}{n} \sum_{1}^{n} x_i$.

The density of (3.2), denoted by $\pi_{a,b}(\theta)$, is called the \textit{inverted gamma density}, since if $\tilde{\theta}$ is a random variable with density $\pi_{a,b}(\theta)$, then $\tilde{\theta}^{-1} = \tilde{\lambda}$ has gamma density (1.5).

We may verify readily that if our initial prior is of the form $\pi_{a,b}(\theta)$, of (3.2) and we use any one of the sampling plans, then the corresponding posterior density is also of the form (3.2). However, the parameter $a$ of the prior is replaced by $a + k$ in the posterior, and the parameter $b$ of the prior is replaced by $b + T$ in the posterior. As before, $k$ denotes the number of observed failures and $T$ is the total time on test. This follows readily from the likelihood expression (3.1) and the fact that in this case $T = \frac{1}{n} \sum_{1}^{n} x_i$ since all lifelengths are observed.

The Mean of the Posterior Density

The mean of the inverted gamma density given in (3.2) is readily
calculated:

\[ \int_0^\infty \theta^{a-1} e^{- \theta} \frac{e^{-b/\theta}}{\Gamma(a)} d\theta = \frac{b}{a - 1} \cdot \]

For the inverted gamma posterior density in which the parameters are \( a + k \) (in place of \( a \)) and \( b + T \) (in place of \( b \)), the corresponding mean takes the form

\[
(3.3) \quad \frac{b + T}{a + k - 1} = (1 - w) \frac{b}{a - 1} + w \frac{T}{k},
\]

where \( w = k/(k + a - 1) \). Thus the mean of the posterior density may be written as a convex combination of the prior mean \( b/(a - 1) \) and the maximum likelihood estimate \( T/k \) of the exponential life distribution mean. Note that as \( k \), the number of observed failures increases, the posterior mean attaches more weight to the MLE of the true mean and less weight to the prior mean.

Table 3.1 summarizes the properties of the natural conjugate prior density and of the corresponding posterior density for the two different parametrizations of the exponential model.

**Note:** $k$ = number of observed failures, 
$T$ = total time on test.
Arbitrary Prior Density

In our analysis up to now, we have focused mostly on the case in which the prior density is the natural conjugate prior. In this subsection, we expand our consideration to cases in which the prior is not necessarily the natural conjugate prior. We obtain results similar to those holding in the natural conjugate prior case.

Let \( \pi(\theta) \) be a prior density on \( \mathbb{R} \) such that \( \{ \theta \mid \pi(\theta) > 0 \} \) is an interval on \( [0, \infty) \). We show in Appendix A of this chapter that

\[
(3.4) \quad P[\theta > \theta_0 \mid k, T] = \int_{\theta_0}^{\infty} \pi(\theta \mid k, T) \, d\theta
\]

is decreasing\(^{\dagger}\) in \( k > 0 \) for fixed \( T \) and increasing\(^{\dagger}\) in \( T \) for fixed \( k \), i.e., the posterior random variable \( \tilde{\theta} \) is stochastically decreasing in \( k \) and stochastically increasing in \( T \). In particular,

\[
E[\tilde{\theta} \mid k = 0, T] \geq E[\tilde{\theta} \mid k = 0, T = 0] ;
\]

the lower bound is, of course, the mean of the prior density. Thus, observing total time on test \textit{without} observing failures tends to change our belief about \( \theta \) as compared with our prior belief; we tend to believe in a larger \( \theta \). However, for the natural conjugate prior, the variance of \( \tilde{\theta} \) given \( k \) and \( T \), decreases with \( k \) but \textit{increases} with \( T \). Also the coefficient of variation is constant in \( T \) but \textit{decreases with} \( k \). (See Table 3.1.) Hence if \( k = 0 \), large values of \( T \) tend to make us optimistic regarding \( \theta \). However, failures are needed to sharpen the posterior density. Similarly, for \( \tilde{\lambda} = \theta^{-1} \), we

\(\dagger\) Terminology: Throughout the book we use the term "increasing" in place of "nondecreasing" and "decreasing" in place of "nonincreasing."
can show that for a general prior density on $\tilde{\lambda}$ under mild regularity conditions,

$$P[\tilde{\lambda} \geq \lambda_0 \mid k, T]$$

increases in $k$ for fixed $T$ and decreases in $T$ for fixed $k$, just as we would expect.

3.1 Example

Suppose our prior density on $\tilde{\theta}$ is the natural conjugate prior with $a = 4$ and $b = 12$. We put 10 units on test. The earliest failure occurs at $X_{(1)} = 1$, followed by a withdrawal at $t = 2$, and finally a second failure at $X_{(2)} = 3$. In Figure 3.1, we plot the posterior mean, posterior standard deviation, and posterior coefficient of variation as a function of $t$, the test time elapsed. Table 3.1 may be used to generate the plots.

In Figure 3.2 we have plotted the posterior density for $\tilde{\theta}$ at selected times during the life test. The posterior density for $t = 0$ is of course the prior density. Notice the shape of the posterior density at $t = 1^-$ (i.e., just before the first observed failure) and at $t = 1$ (i.e., just after the first failure).

4. NOTES AND REFERENCES

Section 1:

Books which emphasize Bayesian concepts as well as their applications are DeGroot (1970) and Winkler (1972). In a series of papers, D. Basu (1975), (1977), (1978), points out the inadequacy of other approaches to statistical inference. Definition 1.4 of sufficiency is attributed by D. Basu to Kolmgorov (1942). The connection between sample theory (Fisher) sufficiency and Kolmgorov sufficiency is discussed in Shih-Chuan Cheng (1978). Fisher sufficiency implies Kolmgorov sufficiency. The converse is false in general. Natural conjugate priors were introduced by Raiffa and Schlaifer (1961). For a rigorous characterization of natural conjugate priors, see Diaconis and Ylvisaker (1979). The reviews of Bayesian statistics by Lindley (1972) and (1978) present excellent summaries of recent advances in the subject.

Section 2:

Epstein and Sobel (1953), (1954) were the first to investigate the properties of the exponential model applied to life test plans. In a series of papers they made an intensive and extensive study of the statistical features of a variety of exponential procedures for life testing. Their work greatly influenced reliability theory and practice at the time and still strongly influences current statistical practice in reliability. Government Handbook H-108 and its subsequent modifications represent the Government's "seal of approval" and its effort to implement the theory by making readily available tables and graphs for easy use of the exponential model.
Section 3:

Stochastic monotonicity properties of the posterior mean are derived using the concepts and methods of total positivity. (A comprehensive and authoritative treatment of total positivity may be found in Karlin (1968).) Theorem A.1 in the appendix is similar to Lemma 2, p. 74, of Lehmann (1959).

In the mathematical insurance literature formula (3.3) is called the credibility formula. Jewell (1977) and (1978) has discussed Bayesian life testing.

APPENDIX A

POSTERIOR DISTRIBUTIONS CORRESPONDING TO ARBITRARY PRIORS AND LIKELIHOODS WITH THE MONOTONE RATIO PROPERTY

We will prove the results mentioned in Section 3.

A.1 Theorem

Let \( \pi_o(\theta) \) be a prior density on \( \Theta \) such that \( \{ \theta \mid \pi_o(\theta) > 0 \} \) is an interval in \( (-\infty, \infty) \). Let data \( D = (k,T) \) and likelihood \( L(\theta \mid k,T) \) be given such that for \( \theta_1 < \theta_2 \)

\[
L(\theta_1 \mid k,T)/L(\theta_2 \mid k,T)
\]

is increasing in \( k \) and decreasing in \( T \). Let \( g(\theta) \) be increasing in \( \theta \). Then

\[
(A.1) \quad \int_{\Theta} g(\theta)\pi(\theta \mid k,T)d\theta
\]

is decreasing in \( k \) (\( T \) fixed) and increasing in \( T \) (\( k \) fixed). The proof will be given shortly.

A.2 Corollary

If \( L(\theta \mid k,T) \propto \theta^{-k} e^{-T/\theta} \), then

\[
(A.2) \quad P[\theta > \theta_o \mid k,T] = \int_{\theta_o}^{\infty} \pi(\theta \mid k,T)d\theta
\]

is decreasing in \( k \) (\( T \) fixed) and increasing in \( T \) (\( k \) fixed). [See Section 3 and (3.4).]
Proof:

In Theorem A.1, let \( g(\theta) \equiv 1 \) for \( \theta > \theta_o \) and 0 otherwise.

A.3 Corollary

Let \( L(\lambda \mid k,T) \propto \lambda^k e^{-\lambda T} \) and \( g(\lambda) \) be increasing in \( \lambda \). Then

\[
(A.3) \quad \int_0^\infty g(\lambda) \pi(\lambda \mid k,T) d\lambda
\]

is increasing in \( k \) (T fixed) and decreasing in \( T \) (k fixed).

Clearly (A.1) [A.3] implies that all moments of the posterior distribution are decreasing [increasing] in \( k \) and increasing [decreasing] in \( T \).

Proof of Theorem A.1:

For \( \theta_1 < \theta_2 \),

\[
L(\theta_1 \mid k,T)/L(\theta_2 \mid k,T)
\]

increasing in \( k \) implies that for \( k_1 < k_2 \)

\[
L(\theta \mid k_1,T)/L(\theta \mid k_2,T)
\]

is increasing in \( \theta \). It is easy to see that this in turn implies that:

\[
(A.4) \quad \pi(\theta \mid k_1,T)/\pi(\theta \mid k_2,T)
\]

is also increasing in \( \theta \). Let

\[
A = \{\theta \mid \pi(\theta \mid k_1,T) > \pi(\theta \mid k_2,T)\}
\]

and
\[ B = \{ \theta \mid \pi(\theta \mid k_1, T) < \pi(\theta \mid k_2, T) \} . \]

Let \( a = \inf_{\theta \in A} g(\theta) \) and \( b = \sup_{\theta \in B} g(\theta) \). Then the ratio in (A.4) is increasing in \( \theta \) implies that \( a \geq b \).

Now

\[
\int_H g(\theta) [\pi(\theta \mid k_1, T) - \pi(\theta \mid k_2, T)] d\theta
\]

\[
\geq a \int_A [\pi(\theta \mid k_1, T) - \pi(\theta \mid k_2, T)] d\theta
\]

\[
+ b \int_B [\pi(\theta \mid k_1, T) - \pi(\theta \mid k_2, T)] d\theta
\]

\[
= (a - b) \int_A [\pi(\theta \mid k_1, T) - \pi(\theta \mid k_2, T)] d\theta \geq 0 .
\]

Hence, the integral in (A.1) is decreasing in \( k \).

A similar argument proves that the integral in (A.1) is increasing in \( T \).

| First Chapter of book in progress: Data Analysis and Inference in Reliability and Biometry by Richard E. Barlow and Frank Proschan. |

| 20. ABSTRACT                           |                                                                     |
|----------------------------------------|                                                                     |
| This report represents the first chapter of a book in preparation on inference and data analysis in reliability and life testing. The point of view adopted differs from that of most books on the subject in the following basic respect: Prior information available to the reliability analyst is utilized fully in a formal statistical fashion. Experience accumulated in helping engineers, quality assurance managers, scientists, biostatisticians, and others who must make estimates and reach decisions from either planned experiments or retrospective data has shown us that the point of view adopted throughout the book has resulted in useful solutions to real-life problems. By contrast more classical statistical methods have often proven inadequate in many practical problems simply because the data available are insufficient to reach conclusions with a desired degree of assurance. |
The book is intended primarily for actual use by the engineering and scientific practitioner, rather than for theoretical study and philosophical analysis by the statistician. Thus we omit a philosophical justification of the methods presented; rather, we rely on the fact that they have led to useful answers to problems that have arisen in practice.

One final point: Many of the methods and results are original and have not appeared in the literature. This fact has led us to issue the chapters as reports under our research grants.
